Abstract

This research examines whether industry-level stock market responses to the April 2nd, 2025, tariffs, referred to as “Liberation Day”, align with theoretical predictions derived from elasticity value economic models. According to monopolistic elasticity theory, industries with more elastic demand are expected to have greater negative effects from tariffs, while inelastic industries are expected to be less affected. To study this relationship, a capital asset pricing economic model is constructed to calculate the impact of the tariffs using both simple and abnormal stock market returns immediately following the enactment of the tariffs. Industries are then rated on a standardized elasticity scale and compared against their calculated stock market return using the model. Preliminary results reveal a weak negative relationship for both simple and abnormal stock market returns and elasticity. This study found that industries with higher elasticity tended to show more negative stock returns after tariffs, supporting some economic predictions. However, the relationship was weak and inconsistent, suggesting that elasticity alone cannot fully explain market responses. Future research should address limitations such as the lack of country-specific data and the small number of data points. In a similar manner, future research should explore the inclusion of additional variables in economic models to improve policy relevance.

Statement of Goals and Significance

On April 2nd, 2025, the United States enacted a sweeping set of tariffs across every industry, referred to in financial and policy circles as “Liberation Day”. Enacted was a ten percent universal tariff on all imports. This policy event provides a natural economic experiment to test economic theory against real-world stock market responses. Understanding whether price elasticity of demand, which is an economic measure of consumer sensitivity to price changes, can predict stock market behavior at the industry level enhances understanding of how theoretical models translate to markets. While traditional models suggest that industries with elastic demand should be more negatively impacted by tariffs, this study tests that assumption using stock market return data and multiple economic models.

Literature Review

We have sought to understand the role of elasticity in economic modeling and policy analysis in reference to the event on April 2nd, 2025. Current research offers a comprehensive meta-analysis of price elasticity estimates across product categories, contributing a theoretical framework for interpreting consumer responsiveness to price changes (Bijmolt, van Heerde, and Pieters, 2005). Further research extends this framework by explaining the Capital Asset Pricing Model (CAPM) and its in-depth economic applications (Elbannan, 2014). These studies help to establish elasticity as a central concept for evaluating return, which is relevant when assessing the impact of major economic political policies, such as tariffs. The economic consequences of tariffs on market performance have been studied for decades. Early research by (Leith, 1971) explores the effects of trade restrictions on production, consumption, and trade. More recent studies, such as (Glauber, 2025), provide specific tariff repercussion insight to the United States agriculture industry. Even though Glauber’s research focuses on tariff repercussions at an

industry level, there is yet to be comprehensive, industry level research on a majority of the United States industries.

The highlighted gap of knowledge in literature are the impacts of recently enacted tariffs , specifically on April 2nd, 2025, which is commonly referred to as “Liberation Day”. Previously conducted research has articulated a timeline of tariffs during Trump’s term (Kilcrease, 2025), but has not offered insight into the economic repercussions of these tariffs. Given the recency of the event, scholarly research on the topic remains limited. The objective of this paper is to evaluate the extent that the stock market's response to the tariffs enacted on April 2nd, 2025, align with elasticity models. More specifically, this leads to a research question of to what extent does the stock market's response to the 2025 tariffs at the industry-level align with theoretical predictions based on elasticity models? It is noteworthy to mention that when this study mentions elasticity, we are referring to price elasticity of demand in particular. With price elasticity of demand explicitly defined as a measurement of the percentage change in consumer demand due to the percentage change in price.

Methodology

The methodology for this research is conducted through three key steps. First, we construct and define an economic model relating to the returns to elasticity. Second, each industry is rated along a standardized elasticity scale, ranging from most elastic to most inelastic. Finally, we compare the theoretical model’s predictions to the observed stock market value responses across industries. Now, we will discuss the first step in greater detail. As previously analyzed, there exists academic research of theoretical models of elasticity. Research studies include both market characteristics and research methodology to create an estimate for price elasticity (Bijmolt, van Heerde, & Pieters, 2005). Based on these conclusions, we decided to

utilize the Capital Asset Pricing Model (CAPM), (Elbannan, 2014). The model relies on several assumptions developed by (Sharpe, 1964) and (Lintner, 1965), which have been acknowledged and accounted for. The CAPM model utilized in this research is denoted as follows:

$$E[r_i] = r_f + \hat{\beta}_i * (Mkt-RF)$$

The CAPM determines the theoretical rate of return of a specific asset $E[r_i]$, (Elbannan, 2014).

The variables included in the calculation of the theoretical rate of return for this research study are the risk-free treasury rate r_f , the specific industry return change relative to the overall stock market return $\hat{\beta}_i$, and the overall return of the market $Mkt-RF$. For this study, we focused on using the specific industry return changes relative to the overall stock market return $\hat{\beta}_i$. The calculation of $\hat{\beta}_i$ is as follows:

$$\hat{\beta}_i = \frac{\text{cov}(r, Mkt-RF)}{\text{variance}(Mkt-RF)}$$

This calculated $\hat{\beta}_i$ value will be used in the calculations of returns. To fully understand the impacts of the tariffs of “Liberation Day,” we have decided to use four calculations of return. These calculations include simple return for April 3rd, 2025, abnormal return for April 3rd, 2025, simple 2-Day return between April 2nd, 2025 and April 3rd, 2025, and abnormal 2-Day return between April 2nd, 2025 and April 3rd, 2025. To begin, we start with the simple return for April 3rd, 2025. The simple return for April 3rd, 2025, is equivalent to the raw April 3rd, 2025 return from the data source, which is thoroughly outlined in the following sections. There is no direct equation or calculation for this return value. Secondly, the abnormal return for April 3rd, 2025 is equivalent to the simple, or raw, April 3rd, 2025 return minus the expected April 3rd, 2025 return. The expected April 3rd, 2025 return is calculated as follows:

$$\text{Expected April 3}^{\text{rd}}, 2025 = r_f * dt + \hat{\beta}_i * (r_{m(t+1)} - r_f)$$

The variables utilized in the CAPM model remain the same as this model. Therefore, r_f remains the risk-free treasury rate, $\hat{\beta}_i$ remains the same calculation as previously described, and the *Mkt-RF* being the overall return of the market, is now denoted as $(r_{m(t+1)} - r_f)$ to specifically account for April 3rd, 2025. The new variable included in this model is dt , which is equivalent to one business trading day from the year $(\frac{1}{252})$, (Odean, 1999). We use this model to obtain a value, then plug that value into the formula for abnormal return for April 3rd, 2025 to get a final value of return. Now that the simple return for April 3rd, 2025 and abnormal return for April 3rd, 2025 have been calculated, we can transition to the models and calculation for the 2-Day returns. To begin, we start with the simple 2-Day return between April 2nd, 2025 and April 3rd, 2025. Similar to the simple return for April 3rd, 2025, the simple 2-Day return between April 2nd, 2025 and April 3rd, 2025 return is equivalent to the raw 2-Day return between April 2nd, 2025 and April 3rd, 2025. The simple, or raw, 2-Day return between April 2nd, 2025 and April 3rd, 2025 is calculated as follows:

$$\text{Simple 2-Day return} = (1 + r_{i(t-1,t)}) * (1 + r_{i(t,t+1)}) - 1$$

The variable $r_{i(t-1,t)}$ represents the return on April 2nd, 2025 and $r_{i(t,t+1)}$ represents the return on April 3rd, 2025. As expected, the abnormal 2-Day return between April 2nd, 2025 and April 3rd, 2025 follows a similar format to the abnormal return for April 3rd, 2025. The abnormal 2-Day return between April 2nd, 2025 and April 3rd, 2025 is equivalent to the simple, or raw, 2-Day return between April 2nd, 2025 and April 3rd, 2025 minus the expected 2-Day return between April 2nd, 2025 and April 3rd, 2025. The expected 2-Day return between April 2nd, 2025 and April 3rd, 2025 is calculated as follows:

$$\text{Expected 2-Day return} = r_f * 2dt + \hat{\beta}_i * (r_{m(t-1,t+1)})$$

Similar to the expected April 3rd, 2025 formula, we observe that the r_f remains the risk-free treasury rate, $\hat{\beta}_i$ remains the same calculation as previously described, and dt remains equivalent to one business trading day from the year ($\frac{1}{252}$), (Odean, 1999). To account for the two days, the $Mkt-RF$ as the overall return of the market is now denoted as $(r_{m(t-1,t+1)})$, and the two in front of the dt as well. We use this model to obtain a value, then plug that value into the previously mentioned formula for abnormal 2-Day return between April 2nd, 2025 and April 3rd, 2025.

Subsequently, we must explain the data used in these models. The first of the two primary datasets utilized in this research is daily stock market returns for forty-nine different industry portfolios from the Tuck School of Business at Dartmouth. This dataset spans the timeframe of July 1st, 2026 to April 30th, 2025. This dataset maintains the most comprehensive collection of security price, return, and volume data for the NYSE, AMEX and NASDAQ stock markets (French, 2025). Each industry is assigned a NYSE, AMEX, and NASDAQ stock to a portfolio at the end of June each year, then returns are computed from July of that specific year to June of the following year. The data utilizes the Center for Research in Security Prices, LLC (CRSP), which is an affiliate of the University of Chicago Booth School of Business. Additional CRSP files were also included within the research and provide stock indices, beta-based and cap-based portfolios, treasury bond and risk-free rates, mutual funds, and real estate data (French, 2025). Similarly, an additional dataset from the Tuck School of Business at Dartmouth was used, which contained the $Mkt-RF$ data. These return values were used in the calculation of the numerator of $\hat{\beta}_i$ for each individual industry. As previously discussed, the numerator of $\hat{\beta}_i$ is equivalent to $cov(r, Mkt-RF)$. The stock market returns (r), for each industry and the stock market returns for the overall market ($Mkt-RF$) were calculated using this data. Moreover, the overall stock market return values were also used in the calculation of the denominator of $\hat{\beta}_i$ for each individual

industry. As previously discussed, the denominator of $\hat{\beta}_i$ is equivalent to $\text{variance}(Mkt-RF)$.

These two corresponding datasets were crucial in the calculation of $\hat{\beta}_i$. A final, crucial piece of data hails from the United States Department of the Treasury. The risk-free treasury rate, denoted as r_f in the model, comes from the daily treasury bill rate value on April 2nd, 2025. This value was found to be 4.05, and is the value used in the calculations.

To recall, the second step of this research methodology is to rate each industry standardized elasticity scale, ranging from most elastic to most inelastic. Previous research is utilized to complete this step of the research. Broda and Weinstein's study, "Globalization and the Gains from Variety," presents industry-level elasticity estimates, which are denoted as sigma (σ). Broda and Weinstein present a published version of this research as well as an unpublished version of this research. The sigma elasticity values differ in these papers. Therefore, we utilized both the published and unpublished values in this research. The premise driving this decision is that the unpublished elasticity estimates offer both a smaller frame of values and a larger number of data points. Due to the fact that industries were denoted differently in the stock market return dataset (French, 2025), and the standard elasticity estimate dataset (Broda and Weinstein, 2006), the forty-nine different industries from the stock market return data frame were then compared against both the published and unpublished work of Broda and Weinstein to align the industry definitions. The following table outlines each aligned industry notation along with its industry definition used in this research:

Industry Notation	Industry Definition
Aero	Aircrafts
Autos	Automobiles and Trucks
Chips	Electronic Equipment
Clths	Apparel
ElcEq	Electrical Equipment
Food	Food Products
Hardw	Computers
Mach	Machinery
Oil	Petroleum and Natural Gas
Paper	Business Supplies
Softw	Computer Software
Telcm	Communication
Trans	Transportation
Txtls	Textiles

Results

After performing the calculations from the previously discussed models and data, the following graphs were generated to illustrate the results. Graphs were created for all four conditions (simple return for April 3rd, 2025, abnormal return for April 3rd, 2025, simple 2-Day return between April 2nd, 2025 and April 3rd, 2025, and abnormal 2-Day return between April 2nd, 2025 and April 3rd, 2025) with both the published and unpublished elasticity values.

Published Elasticity Value Graphs:

Simple return for April 3rd, 2025:

Abnormal return for April 3rd, 2025:

Simple 2-Day return between April 2nd, 2025 and April 3rd, 2025:

Abnormal 2-Day return between April 2nd, 2025 and April 3rd, 2025:

Unpublished Elasticity Value Graphs:

Simple return for April 3rd, 2025:

Abnormal return for April 3rd, 2025:

Simple 2-Day return between April 2nd, 2025 and April 3rd, 2025:

Abnormal 2-Day return between April 2nd, 2025 and April 3rd, 2025:

Throughout the conditions, we observe that a weak negative relationship was found between returns and industry elasticity. Industries with more elastic demand tended to have

slightly more negative stock returns following the tariff enactment. However, the consistently observed low R-squared values indicate that elasticity explains only a small portion of return variation. From research in the literature review stage, we predicted that relatively high elastic industries such as clothes would display large negative returns. When examining the results by each industry individually, several notable alignments to the models emerge. The clothing and apparel industry (Clths), which has one of the highest elasticities estimates (Broda and Weinstein, 2006), exhibited consistently negative returns across all eight condition calculations. This is consistent with theoretical expectations that industries with highly elastic demand are more vulnerable to changes influenced by tariffs. The computer hardware (Hardw) and software (Softw) industries, which also possess a relatively elastic demand, experienced stock market return declines, further reinforcing the theoretical prediction. In contrast, industries such as petroleum and business supplies (Paper) and food products (Food), which have lower elasticity scores, demonstrated slightly positive returns. These results suggests that these industries may have a more stable demand when shocking policy changes in tariffs occur. However, the observed relationships were not universally consistent across all sectors. For example, the machinery (Mach) and electrical equipment (ElcEq) industries displayed returns that deviated from their expected responses based on elasticity values. In some conditions, industries with less elasticity, such as electronic equipment (Chips), saw stronger declines than more elastic industries.

Discussion and Future Implications

The results of this study partially align with the classical economic predictions derived from elasticity theory. Specifically, industries identified as highly elastic, such as clothing (Clths), exhibited more pronounced negative stock market reactions following the enactment of

the tariffs. This observation supports the theoretical assumption that elastic industries are more sensitive to price increases, as consumer demand declines in response to higher prices. However, the strength of this relationship was weak, as evidenced by low R-squared values across all conditions for return. Furthermore, several industries deviated from theoretical expectations, suggesting that while elasticity may contribute to observed variation in returns, it is insufficient on its own to explain the broader patterns of stock market returns. The inconsistency of these results highlight possible other underlying variables to this research.

While the results offer some insight into the dynamics of influence of tariffs and stock market return, these results indicate limitations of this research. One major limitation of this research is that it is not country specific. To illustrate this issue, Bangladesh and Vietnam are large exporters of textiles into the United States, therefore, we would expect the textiles industry to have a significantly large negative effect opposed to other countries. There is no country specific data included within the models or the data sets. Even though both the published and unpublished elasticity estimates were included within this research from Broda and Weinstein, there still remains a small number of observations included within the data. This small number of observations leads to less statistical power when offering results. As discussed in the results section, some industry reactions matched elasticity model predictions, however many did not, which could indicate that elasticity alone does not fully account for changes in the stock market behavior. Another prominent limitation within this research is that the response to the “Liberation Day” tariffs only account for short-term returns and may not capture the long-term policy impact.

Given the limitations identified in the study, future research should aim to expand on specific details of this study. The tariffs that were enacted on “Liberation Day” were reciprocal. A reciprocal tariff policy is one that matches the tariff amount a country placed on imports from

the United States. Even though there was a ten percent increase for all industries for all countries on “Liberation Day,” countries overall tariff policy in regard to the United States may have been different from one another. Further research into country specific tariff policies on this day would be valuable for the future in this research. Implications of this research extends towards policy design and implementation considering the policy influence of tariffs was the main focus of the research question. Policymakers should consider industry elasticity as a factor when projecting economic response from trade policies, however, other confounding variables must also be accounted for. This gap within this study allows further research to explore alternate or additional variables to be included within these models.
